INTERACTION OF CHRONIC STRESS WITH SEROTONIN TRANSPORTER AND CATECHOL-O-METHYLTRANSFERASE POLYMORPHISMS IN PREDICTING YOUTH DEPRESSION

Christopher C. Conway, M.A.,1* Constance Hammen, Ph.D.,1 Patricia A. Brennan, Ph.D.,2 Penelope A. Lind, Ph.D.,3 and Jake M. Najman, Ph.D.4

Background: Investigations of gene–environment interaction (G × E) in depression have implicated a polymorphism in the promoter region of the serotonin transporter gene (5-HTTLPR) as a moderator of the stress–depression relationship. However, recent evidence for 5-HTTLPR G × E in depression has been inconsistent. This study examined the moderating effect of the val158met polymorphism in the catechol-O-methyltransferase (COMT) gene on the strength of 5-HTTLPR G × E. Methods: A community sample of youth (n = 384) was genotyped for 5-HTTLPR and COMT. A multi-method, multi-informant index of chronic family stress was derived from interviews and questionnaires administered at youth age 15. G × G × E was examined in relation to depression diagnoses between ages 15 and 20 and depressive symptoms at age 20. Results: Significant three-way interactions were observed for both depressive symptoms and diagnoses, such that 5-HTTLPR G × E occurred only in the context of COMT val158 allele homozygosity. For val158 homozygotes, the 5-HTTLPR LL genotype exerted a protective effect in the face of stress. No genetic main effect or two-way G × E was found for 5-HTTLPR. Conclusions: Inconsistent 5-HTTLPR G × E findings to date may be partly attributable to unmeasured epistatic effects between 5-HTTLPR and COMT val158met. Identifying the conditions under which 5-HTTLPR G × E is most likely to operate may allow depression prevention and treatment efforts to target youth at highest risk.

Metabolism. Methodological requirements that should be met. The met158 allele produces a heat-labile enzyme amino acid substitution commonly known as valine (Val) to methionine (Met). The met158 allele is thought to confer vulnerability to stress because it is associated with increased stress hormone release, as well as greater sensory and affective ratings of pain, in response to physical and psychological stressors. Additionally, the met158 variant is consistently linked to increased activation in the amygdala and hippocampus, as measured by functional magnetic resonance imaging, following exposure to unpleasant and emotional visual stimuli.

COMT-mediated dopamine increases in limbic regions are hypothesized to result in enhanced arousal and exaggerated affective responses to environmental stressors. A “case-only” study of Italian inpatients diagnosed with affective disorders offered preliminary evidence that the met158 allele increases susceptibility to depression following adverse events. This study examined the moderating effect of COMT genotype on 5-HTTLPR × chronic stress interactions in an Australian community sample of adolescents. Exposure to chronic family stress was indexed by a multi-method, multi-informant composite score from age 15 assessments. Depressive symptoms and diagnoses were assessed five years later at youth age 20. A gene–gene–environment interaction (G × G × E) was predicted such that the strength of 5-HTTLPR G × E would depend on COMT genotype. Specifically, carriers of both the 5-HTTLPR S and COMT met158 alleles were predicted to exhibit the greatest depressive response to chronic stress, whereas those homozygous for L and val158 alleles were predicted to be the least reactive to stress.

**MATERIALS AND METHODS**

**PARTICIPANTS**

Participants were recruited from the Mater-University Study of Pregnancy, which followed a birth cohort of 7,223 mothers and their offspring born between 1981 and 1984 in Brisbane, Australia. Mothers completed the Delusions-Symptoms-States Inventory during pregnancy, post-partum, 6 months after birth, and 5 years after birth. As described in detail elsewhere, this study selected and followed up 815 of the original families when the child reached age 15, oversampling for mothers with a putative history of depression based on the severity and chronicity of depressive symptoms endorsed on the DSSI whose diagnostic status was later confirmed. The sample studied at age 15 was 92% Caucasian and 8% minority (Asian, Pacific Islander, and Aboriginal), with median family income falling in the lower middle class and mothers’ median education level at grade 10. At youth age 20, all families were invited to participate in a second assessment, yielding a sample of 705 youth and mothers that agreed and completed further interviews and questionnaires (see for details).

Of the 705 youth assessed at age 20, 512 provided blood samples between ages 22 and 25. Participants not providing DNA either had withdrawn from follow-ups, declined the current study, moved, had major medical problems, or were deceased. The 512 participants in the genotyping sample at ages 22-25 did not differ from the 303 participating at age 15 but not at ages 22-25 in terms of youth depression history by age 15 or maternal history of depression by age 15, χ² < 1, P = .10, but were less likely to be male, χ²(1, 815) = 21.29, P < .01.

The current analyses are based on 384 randomly selected DNA samples from the 512 participants who provided blood because...

A variety of indicators of family stress were collected in order to adequately capture aspects of both the marital and parent-child relationship, as well as incorporate multiple informants (i.e. parent, youth, interviewer) and methods (i.e. interview-report questionnaire and interview). Three measures were interviewer-rated scores from the youth and mother versions of the UCLA Chronic Stress Interview [51] covering quality of mother's marital/romantic relationship, her relationship with the youth, and the youth's relationship with immediate family members. Intraclass correlations based on independent ratings of these domains were 0.82, 0.82, and 0.76, respectively. Validity data for adults and youth are reported elsewhere [51,52].

To assess overall marital relationship quality, the Satisfaction subscale of the Dyadic Adjustment Scale (DAS; [53]) was administered to mothers who were in relationships, as well as husbands when available. Mothers and fathers also completed the Modified Conflict Tactics Scale (MCTS; [49]) assessing psychological and physical coercion (e.g. argued heatedly; refused to talk; threw something; hit partner). Cronbach’s $\alpha$ for the DAS and MCTS ranged from 0.80 to 0.95 and from 0.79 to 0.92, respectively, across parents.

The Children’s Report of Parental Behavior Inventory (CRPBI; [55]) was administered to youths to assess the quality of their interactions with both parents. The psychological control versus psychological autonomy and youth’s perception of acceptance versus rejection were the two subscales of the CRPBI used in the current analyses. Internal consistency for each subscale by parent ranged from 0.77 to 0.91.

Each of these 11 measures was standardized across the sample and non-missing variables for each participant were averaged to form a composite ($\alpha = .78$). Scores ranged from −1.25 to 1.99 ($M = 0.01$, $SD = 0.57$), with higher values indicating greater family stress.

### GENOTYPING

Participants who agreed to the blood collection study were mailed consent forms, a blood collection pack, and questionnaires, and were instructed to have the blood drawn at a local pathology laboratory. The blood samples were picked up by courier from the individual and transported to the Genetic Epidemiological Laboratory of the Queensland Institute of Medical Research, where the genotyping procedures were conducted.

Assays for the COMT val158met SNP were designed using MassARRAY Assay Design software (version 3.0; Sequenom Inc., San Diego, CA) and typed using iPLEXTM chemistry on a Compact MALDI-TOF Mass Spectrometer (Sequenom). Forward and reverse PCR primers and a primer extension probes were purchased from Bioneer Corporation (Daejeon, Korea). Genotyping was carried out in standard 384-well plates with 12.5 ng genomic DNA used per sample. A modified Sequenom protocol was followed, using half
reaction volumes in each of the PCR, SAP, and iPLEX stages giving a total reaction volume of 5.5 μL. The iPLEX reaction products were desalted by diluting samples with 18 μL of water and 3 μL SpectroCLEAN resin (Sequenom) and then were applied to a Compact MALDI-TOF Mass Spectrometer by MassARRAY Workstation software (version 3.3) (Sequenom). Allele calls for 384-well plates were reviewed using the cluster tool in the SpectroTYPER software (version 3.3; Sequenom) to evaluate assay quality. In this sample, genotype frequencies (and corresponding proportions) at val158met were VV = 91 (.24), VM = 195 (.51), MM = 95 (.25), and were in Hardy–Weinberg Equilibrium, \( \chi^2(1, 381) = 0.04, \ P = .83 \).

The 5-HTTLPR 43-bp deletion polymorphism was assayed using previously reported methods. Most samples were subjected to triplicate gel analysis. A minimum of two independent results in agreement was required for inclusion, which gave a final call rate of 96.4%. In this sample, the genotype frequencies (and proportions) were LL = 122 (.32), LS = 178 (.47), and SS = 81 (.21), and in Hardy–Weinberg equilibrium, \( \chi^2(1, 381) = 1.61, \ P = .20 \).

The minor allele of the rs25531 SNP in the L allele has been adopted in the original analyses. The minor allele of the rs25531 SNP in the L allele has been reported to render the L allele functionally equivalent to S.\[^{[56]}\] This SNP was assayed using the protocol of Wray et al.\[^{[56]}\] and these analyses were performed reclassifying L\(_C\) alleles as S.

### STATISTICAL ANALYSIS

The effects of 5-HTTLPR, COMT, chronic family stress, and their two- and three-way interactions on age 20 depressive symptoms (BDI) were estimated using ordinary least-squares (OLS) regression. Gender, maternal depression history, and youth depression history at age 15 were included in the model as covariates. One dummy variable was created to represent the contrast of the LL group versus SS and SL groups, consistent with past research on 5-HTTLPR and stress reactivity.\[^{[57]}\] Similarly, met158 carriers were grouped and contrasted with val158 homozygotes in accordance with prior research (e.g.\[^{[44]}\]).

Given these groupings, four genotype combinations were possible: S allele carriers and met158 allele carriers (hereafter SM), S allele carriers and val158 homozygotes (SV), L allele carriers and met158 allele carriers (LM), and L allele carriers and val158 homozygotes (LV).

Using an estimated effect size of \( \Delta R^2 = 0.02 \) drawn from previous G × G × E research,\[^{[56]}\] a Type I error rate of 0.05, and a desired power level of 0.80, power analyses in Stata 10.0\[^{[56]}\] indicated that 324 observations were needed to detect a three-way interaction between 5-HTTLPR, COMT, and family stress, given that one exists.

The same set of predictors was entered in a logistic regression model with youth depression onset between ages 15 and 20 years as the outcome variable. OLS and logistic regression parameters were compared to confirm that any observed interactions were not artifacts of measurement scale.\[^{[57]}\] For both models, when interactions were detected, simple effects were calculated using the LINCOM command in Stata 10.0.\[^{[56]}\] Simple effect \( F \)-values (denoted \( p_{adj} \)) were adjusted following the procedures formulated by Benjamini to control the False Discovery Rate for correlated test statistics.\[^{[56]}\]

### RESULTS

#### GENE–ENVIRONMENT CORRELATION

Univariate analysis of variance revealed no main effects of 5-HTTLPR, \( F(1,356) = 0.57, \ P = .45 \), or COMT val158met, \( F(1,356) = 1.63, \ P = .20 \) on exposure to family stress, nor was there any joint effect of 5-HTTLPR and COMT, \( F(1,356) = 1.38, \ P = .24 \).

### 5-HTTLPR × COMT × FAMILY STRESS ON DEPRESSIVE SYMPTOMS

Predictors were entered hierarchically, with main effects on Step 1, two-way interactions on Step 2, and the three-way interaction on Step 3. A significant main effect of chronic family stress was observed on Step 1, whereas neither 5-HTTLPR nor COMT exerted a direct effect on BDI (see Table 2). The addition of the two-way interactions on Step 2 did not account for a significant increment in variance explained, \( \Delta R^2 = 0.006, \Delta F(3,332) = 0.81, \ P = .49 \), indicating no \( G \times E \). In contrast, on Step 3, the three-way interaction term was significant, \( b = -11.04, \ SE = 3.73, \ P < .01 \).

For the LV group, the slope of BDI scores on chronic family stress was not significantly different from 0, \( b = -3.25, \ SE = 2.50, \ p_{adj} = .24 \). All other genotype groups exhibited significant positive slopes of BDI on chronic stress (SV, \( b = 6.75, \ SE = 1.80, \ p_{adj} < .05 \); SM, \( b = 3.84, \ SE = 1.06, \ p_{adj} < .05 \); LM, \( b = 4.88, \ SE = 1.88, \ p_{adj} < .05 \) (see Fig. 1). Furthermore, the slope of the LV group was significantly different from the slopes for the other three genotype groups (all \( p_{adj} < .05 \)), whereas the three groups with nonzero slopes did not differ from each other in terms of strength of the chronic stress–BDI association (all \( p_{adj} > .10 \)).\[^{[2]}\]

\[^{[2]}\] Exploratory analyses were performed using an additive model for 5-HTTLPR, coding a single variable with values of 0, 1, and 2 to represent the number of S alleles present. The three-way interaction remained significant in predicting depressive symptoms, \( b = -6.05, \ SE = 2.72, \ z = -2.22, \ P < .05 \). The slope of depression on stress was comparable in the SS and SL groups (\( P > .05 \)), regardless of COMT genotype, consistent with the dominant model of the 5-HTTLPR S allele adopted in the original analyses.
**5-HTTLPR × COMT × FAMILY STRESS ON DEPRESSION DIAGNOSES**

As in the linear model, variables were entered hierarchically into the regression. In Step 1, 5-HTTLPR and COMT did not significantly affect the probability of being diagnosed with depression between ages 15 and 20, whereas increasing stress was associated with a greater likelihood of depression (see Table 3). On Step 2, there was no effect of the two-way interactions, taken together, on depression risk, \( \chi^2(3) = 0.24, P > .10 \). Consistent with the OLS model, on Step 3 the three-way interaction term was significantly less than 0, \( b = -2.40, SE = 1.13, Wald = 4.41, P < .05 \). As shown in Figure 2, the form of this interaction was nearly identical to that observed in the OLS model. Again, the LV group was resilient to increasing stress, \( b = -0.62, SE = 0.73, z = -0.85, P_{adj} = .39 \). In contrast to the LV group, all other genotype combinations showed a positive relationship between chronic family stress and likelihood of depression.

depression; however, P-values of all the corresponding simple slopes fell short of significance after adjustment for multiple testing (LM, $b = 1.30$, $SE = 0.61$, $p_{adj} = .13$; SV, $b = 0.83$, $SE = 0.55$, $p_{adj} = .27$; SM, $b = 0.37$, $SE = 0.29$, $p_{adj} = .28$).  

**DISCUSSION**

This study examined the joint effect of 5-HTTLPR and COMT val158met on depressive reactions to chronic stress in a sample of adolescents. COMT genotype—previously linked to stress sensitivity—and depressive disorders were observed only among val158 homozygotes. In the context of val158 homozygosity, the 5-HTTLPR LL genotype was associated with resilience to stress, relative to the SL and SS genotypes. However, in the presence at least one met158 allele, both 5-HTTLPR genotype groups were vulnerable to depressogenic stressors.

These results are consistent with past investigations that have linked the 5-HTTLPR S and COMT met158 variants to emotional reactivity to environmental stress (see\[^{[7,41]}\]). The presence of at least one of these susceptibility alleles was sufficient to increase risk for depression in response to stress. On the other hand, the current findings do not support the view that 5-HTTLPR L homozygotes are immune to pathogenic environments. When paired with a met158 allele, L homozygosity provided no protective effect against chronic stressors. This pattern of results may be attributable to heightened affective arousal experienced by carriers of the S or met158 allele when confronted with stressful conditions.\[^{[40,41]}\] The presence of either one of these variants has been shown to be sufficient to increase neural and psychophysiological reactivity to aversive cues.\[^{[40,37]}\]

Contrary to hypotheses, the met158 allele did not potentiate the effect of the S allele on depressogenic reactivity. Biological mechanisms underlying the lack of additivity between met158 and S are unclear, but may be elucidated by future research into the interaction of serotonergic and dopaminergic neurotransmitter systems (e.g.\[^{[63,64]}\]).

The current G $\times$ E findings may be relevant to discrepancies among existing reports of 5-HTTLPR $G \times E$. Some studies have failed to replicate the $G \times E$ observed by Caspi et al.\[^{[6]}\] and recent null meta-analytic findings\[^{[16,17]}\] have called attention to this inconsistency (cf.\[^{[18–20]}\]). Indeed, in the current analyses the moderating effect of 5-HTTLPR was detected only when COMT and 5-HTTLPR were analyzed simultaneously. Thus, one of several possible explanations for conflicting results in the literature is that the nature of 5-HTTLPR $G \times E$ is dependent on the background of other genes, including COMT, regulating sensitivity to stress.

These results should be considered preliminary in light of the limited sample size available for the genetic analyses. The group homozygous for the L and val158 alleles, in particular, was relatively small ($n = 29$). Thus, it is possible that this study was underpowered to detect a significant effect of family stress in this group, although there was no evidence of a trend in this direction. This is potentially important given that the null stress–depression association in the LV group, relative to the strong depressogenic effect of stress obtained in all other genotype combinations, appeared to account for the observed $G \times G \times E$. It is possible that results could differ in larger samples, and conclusions should be considered tentative until replications from large-scale studies, with more representative samples of all genotype combinations, are available.

Several other limitations of this study should be noted. First, depression outcomes were assessed over a limited age range (i.e. late adolescence). This may be an important qualification of the results in light of apparent fluctuations in $G \times E$ across developmental stages.\[^{[14,63]}\] Second, the current study controlled for gender, but future studies with sufficiently large samples should explore whether complex gene–gene interactions may apply differently for males and females.\[^{[64,65]}\] Third, sample size limitations prevented a thorough investigation of the role of heterozygosity at 5-HTTLPR and COMT. Further research is necessary to determine whether additive, dominant, or recessive models for these loci are most appropriate for $G \times E$ designs. Finally, gene–environment correlation (rGE) presents potential complications in the interpretation of $G \times E$ in studies of measured genes and measured environments.\[^{[32]}\] In this sample, tests for rGE indicated that exposure to chronic family stress was not associated with genotype. However, it is implausible that the family context is entirely independent of genetic contributions, so the possibility remains that some portion of the observed interactions reflects unmeasured $G \times G$.

Future research is necessary to explore the mechanisms, timing, and continuity of stressors in 5-HTTLPR $G \times E$. In this study, chronic stress was assessed 5 years prior to the self-reported depressive symptoms. The plausibility of $G \times E$ operating over this interval is supported by evidence suggesting relatively high stability of chronic stress exposure over time.\[^{[66]}\] However, given the association of chronic stress in adolescence with early childhood adversity as well as acute stressors proximal to the age 20

\[^{3}\text{Follow-up analyses were performed exclusively in a subsample of 354 Caucasian participants (i.e. 93.0% of the genotyped sample) to ensure that ethnic stratification did not affect the findings. Results from the OLS model revealed that the three-way interaction remained significant, } b = 10.35, SE = 4.01, z = 4.02, P < .01. \text{ Similarly, the strength of the } G \times G \times E \text{ in the logistic model was not affected, } b = 2.66, SE = 1.16, z = 2.29, P < .05. \text{ Furthermore, the nature of these interactions was equivalent to that observed in the full sample; in all cases, the significance of simple slopes was unchanged.} \]
assessment, it remains to be seen whether chronic family stress exerts a unique influence in 5-HTTLPR G × E (see ). Future studies using psychometrically sound measures of acute stress and early adversity are needed to explore the range of G × E effects involving 5-HTTLPR and COMT.

In summary, these preliminary results raise the possibility that the effect of 5-HTTLPR on depressive reactivity to life stress may be more reliably detected by simultaneously accounting for variation in other monoaminergic genes that underlie stress reactivity. The current findings of complex gene–environment interplay await replication in future research involving large samples. By identifying the biological and psychological moderators of 5-HTTLPR G × E, the conditions in which G × E is most likely to operate can be better understood.

Acknowledgments. The authors greatly appreciate the assistance of Robyne LeBroque, Cherri Dalton Comber, and Sascha Hardwicke (project coordinators) and their interview staff. We also thank the staff of the Genetic Epidemiological Laboratory of the Queensland Institute of Medical Research: Professor Nick Martin (Head) for cooperation and access, Michael James for 5-HTTLPR genotyping, and Megan Campbell and Dixie Statham who coordinated genetic data collection and analysis. We extend our thanks also to the original Mater–University Study of Pregnancy principals, William Bor, M.D., Michael O’Callaghan, M.D., and Professor Gail Williams. This study was supported by NIMH R01 MH52239 to Brennan, Hammen, and Najman.
